In Ref. 1, we reported an estimate of the critical exponent for the divergence of the localization length at the quantum Hall transition that is significantly larger than those reported in the previous published work of other authors. In this paper, we update our finite size scaling analysis of the Chalker-Coddington model and suggest the origin of the previous underestimate by other authors. We also compare our results with the predictions of Lütken and Ross.[2]

Keywords: quantum Hall effect; Chalker-Coddington model; critical exponent.

PACS numbers: 73.43.±f, 71.30.+h

1. Introduction

When a strong magnetic field is applied perpendicular to an ideal two dimensional electron gas the kinetic energy of the electrons is quantized according to the formula $E_n = (n+1/2)\hbar\omega$. Here, n is a non-negative integer and ω is the cyclotron frequency $\omega = eB/m$. These Landau levels are highly degenerate and the density of states becomes a series of equally spaced delta functions. This degeneracy is broken by disorder and the Landau levels are broadened into Landau bands. Most of the electron states are Anderson localized with the exception of the states at the center of the Landau level where the localization length ξ has a power law divergence described by a critical exponent ν

$$\xi \sim |E - E_c|^{-\nu} \ . \tag{1}$$

When the Fermi level is in a region of localized states, the Hall conductance is quantized in integer multiples of e^2/h. This effect is known as the quantum Hall effect.[3,4] Transitions between consecutive quantized values occur when the Fermi level passes through the center of a Landau band. This is a quantum phase transition. It is characterized by a two critical exponents. One is the critical exponent

ν mentioned above and the other is the dynamic exponent z, which describes temperature dependence.

The quantum Hall transition has been the subject of careful experimental study. The inverse of the product of the critical and dynamic exponents, $\kappa = 1/\nu z$, has been measured very precisely (see Table 1). The value of this product appears to be quite universal; the same value has been obtained in measurements in an $\mathrm{Al}_x\mathrm{Ga}_{1-x}\mathrm{As}$ heterostructure[5] and in graphene.[6] The main problem is that an independent measurement of the dynamic exponent is needed to disentangle the values of the two exponents and, unfortunately, this has been measured much less precisely.

The quantum Hall transition has also been the subject of numerous numerical studies in models of non-interacting electrons. In earlier work, a consensus was reached (see Table 2) that $\nu \approx 2.4$ in apparent agreement with experiment. However, in 2009, we published[1] a numerical analysis of the Chalker-Coddington model in which we found a value of the exponent that was about 10% larger; a result which has since been confirmed by other authors (see Table 3). There now seems to be a consensus that the previous numerical work underestimated the exponent and the apparent agreement with experiment was a coincidence of errors. Below we discuss the reason for the previous underestimate of the exponent.

Table 1. Experimental values of critical exponents for the quantum Hall transition.

	$\kappa = 1/z\nu$	ν	z
Experiment of Li et al.[5] ($\mathrm{Al}_x\mathrm{Ga}_{1-x}\mathrm{As}$)	$0.42 \pm .01$	≈ 2.38	≈ 1
Experiment of Giesbers et al.[6] (graphene)	$0.41 \pm .04$	-	-

Table 2. Earlier estimates of the critical exponent ν.

Chalker and Coddington[7]	$2.5 \pm .5$	Huckestein and Kramer[8]	$2.34 \pm .04$
Mieck[9]	$2.3 \pm .08$	Huckestein[10]	$2.35 \pm .03$
Huo and Bhatt[11]	$2.4 \pm .1$	Lee and Wang[12]	$2.33 \pm .03$
Cain et al.[13]	$2.37 \pm .02$		

Table 3. Recent estimates of the critical exponent ν.

Slevin and Ohtsuki[1]	$2.593[2.587, 2.598]$	Obuse et al.[14]	$2.55 \pm .01$
Dahlhaus et al.[15]	$2.576 \pm .03$	Amado et al.[16]	$2.616 \pm .014$

Another issue concerns the value of the dynamic exponent. For models of non-interacting electrons the dynamic exponent is known exactly, $z = 2$. However, this value cannot be compared directly with the experiment. Burmistrov et al.[17] have emphasized the distinction between the different dynamical exponents that occur in the problem. In the experiment of Li et al.[5] it seems clear that the dynamic exponent that is being measured describes the divergence of the phase coherence length on approaching zero temperature

$$\ell_{\varphi} \sim T^{-z} \; . \tag{2}$$

It also seems reasonably safe to suppose that electron-electron interactions are the source of the electron dephasing. This does not mean however that electron-electron interaction are relevant in the renormalization group (RG) sense and that the quantum Hall transition is described by a fixed point in a theory of interacting electrons. A clear discussion of this can be found in Ref. 17. Also, as described in Ref. 18, it is thought that short range interactions are irrelevant in the RG sense and that only long range Coulomb interaction are relevant and would drive the system to a different interacting fixed point.

It has been pointed out to us by Alexei Tsvelik, that the value of the exponent we have found for the Chalker-Coddington model is very close to that predicted by Lütken and Ross. In a series of papers (Ref. 2 and references therein) these authors have argued that modular symmetry strongly constrains the possible critical theories of the quantum Hall transition. While we cannot claim to understand the details of the theory of Lütken and Ross, we attempt below to compare some of their key predictions with the results of our finite size scaling analysis.

2. Method

We calculated the Lyapunov exponents of the product of the transfer matrices for the Chalker-Coddington model.[7] This model describes electron localization in a two dimensional electron gas subject to a very strong perpendicular magnetic field. The basic assumption is that the random potential is smooth on the scale of the magnetic length. The electron wavefunctions are then concentrated on equipotentials of the random potential with tunneling between equipotentials at saddle points of the potential. In the Chalker-Coddington model this system is modeled by a network of nodes and links. A parameter x, which is essentially the energy of the electrons measured in units of the Landau band width relative to the center of the Landau band, fixes the tunneling probability at the nodes. A random phase distributed uniformly on $[0, 2\pi)$ is attached to each link to reflect the random length of the contours of the potential. For further details we refer the reader to the original article of Chalker and Coddington[7] and to the more recent review by Kramer et al.[19]

We considered the transfer matrix product associated with a quasi-one dimensional geometry with N nodes in the transverse direction and L nodes in the longitudinal direction.[a] The Lyapunov exponents of this random matrix product were

---

[a] For the detailed formulae see Ref. 1.

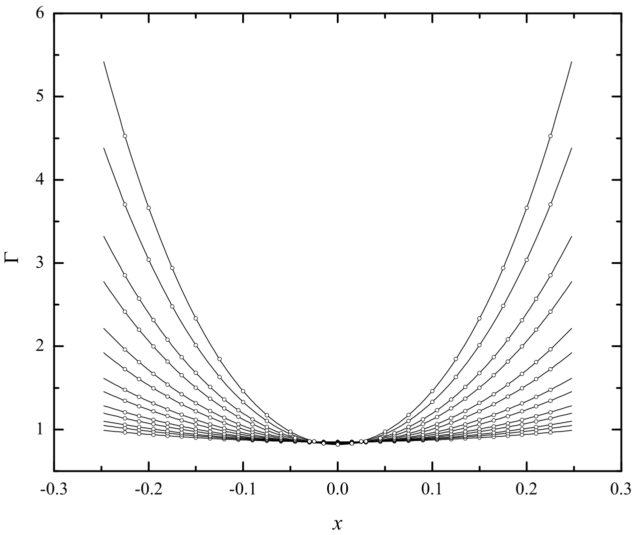

Fig. 1. The product Γ of the smallest positive Lyapnuov exponent γ and the number of nodes in the transverse direction $N = 4, 6, 8, 12, 16, 24, 32, 48, 64, 96, 128, 192, 256$ for the Chalker-Coddington model. The error in the data is much smaller than the symbol size. The lines are even order polynomial fits to the data for each N.

estimated using the standard method.[20,21] The Lyapunov exponents are defined by taking the limit $L \to \infty$. By truncating the matrix product at a finite L, an estimate of the Lyapunov exponents was obtained. The sample to sample fluctuations of this estimate decrease with the inverse of the square root of L. We performed a single simulation for each pair of x and N and truncated the transfer matrix product at a value of L that allowed estimation of the smallest positive Lyapunov exponent γ with a precision of 0.03%, except for the largest values of $N = 192$ and 256 where the precision was relaxed to either 0.05% or 0.1%. To ensure that simulations for different pairs of x and N were independent, we used the Mersenne Twister pseudo-random number generator MT2203 of Matsumoto et al.[22] provided in the Intel Math Kernel Library. All the simulations used a common seed. Independence was ensured by the use of a unique stream number for each simulation. We imposed periodic boundary conditions in the transverse direction for which choice the Lyapunov exponents are even functions of x. It is known that there is a critical point at the center of the Landau band, $x = 0$, and that, when the Fermi energy is driven through this point, the transition between Hall plateaux occurs.

To extract estimates of critical exponent and other quantities we used finite size

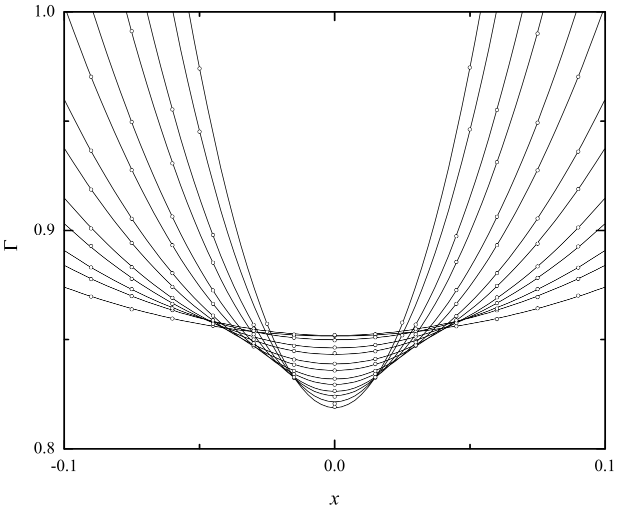

Fig. 2. The same data as in Fig. 1 but focussing on the critical point at $x = 0$. The residual variation of Γ with N at $x = 0$ is due to irrelevant scaling variables.

scaling.[b] In this method, the behavior of the dimensionless quantity

$$\Gamma\left(x,N\right) = \gamma N \ , \tag{3}$$

is analyzed as a function of both x and N. In the absence of any corrections to scaling we would expect this behavior to be described by the following finite size scaling law

$$\Gamma = F\left(N^{2\alpha}x^2\right) \ , \tag{4}$$

where F is an a priori unknown but universal scaling function and

$$\alpha = 1/\nu \ . \tag{5}$$

Note that we have imposed the condition that Γ must be an even function of x.

The actual behavior of Γ as a function of x for different N is shown in Fig. 1 and, in more detail around $x = 0$, in Fig. 2. (The lines in the figures are polynomial fits. They will be discussed below.) According to Eq. (4) curves for different N should have a common crossing point at $x = 0$. However, it is clear from Fig. 2 that this is only approximately correct and that Γ is not exactly independent of N at $x = 0$ but varies by a several percent over the range of N studied. These corrections to scaling arise because of the presence of irrelevant scaling variables. These are variables with negative scaling exponents. Their effect is negligible for large N but their presence may lead to significant corrections at small N. This is consistent with what we see in Fig. 2.

---

[b] This method was first applied to Anderson localization at about the same time by Pichard and Sarma[23,24] and by MacKinnon and Kramer[21,25]. See Ref. 26 for a pedagogical discussion.

To take account of corrections to scaling, we follow Ref. 27 and Ref. 28 and generalize the finite size scaling law

$$\Gamma = F\left(N^{2\alpha} v_0(x), N^{y_1} v_1(x), N^{y_2} v_2(x), \cdots\right) \; . \tag{6}$$

In Eq. (6), v_0 is the relevant scaling variable and $v_1, v_2, \cdots$ are the irrelevant scaling variables. The associated exponents $y_1, y_2, \cdots$ are negative. The inclusion of irrelevant corrections permits the residual N dependence at $x = 0$ seen in Fig. 2 to be modeled. This form also allows for additional corrections due to non-linearities of the scaling variables as functions of x. To impose the condition that Γ must be an even function of x we restrict all the scaling variables to be even functions of x. In addition, since the critical point is at $x = 0$, we impose the condition that $v_0(0) = 0$. To fit the data, the function F is expanded as a Taylor series in all its arguments, and similarly the scaling variables. The coefficients in the Taylor series, together with the various exponents, play the role of fitting parameters.[c] The orders of truncation of the Taylor series are chosen sufficiently large to obtain an acceptable fit of the data (as measured using the χ^2-statistic and the goodness of fit probability). We have attempted this procedure with both one and two irrelevant corrections. Unfortunately, a stable fit of the data has eluded us. We have found that several fits of the data are possible. However, these fits do not yield mutually consistent estimates of the critical exponent.

3. Rudimentary finite size scaling

To circumvent the difficulties described in the previous section we resorted to a less sophisticated approach in which we abandoned the attempt to fit all the data in a single step. Instead, we fitted the data for each N independently to an even polynomial of x. For each N the order of the polynomial was chosen just large enough to give an acceptable goodness of fit. For $N = 4$, a quadratic was sufficient, while for $N = 256$ a sixth order polynomial was required. From these polynomials we estimated the curvature C of Γ at $x = 0$. The results are plotted in Fig. 3. The precision of the estimation of the curvature varies between 0.07% and 0.28%. According to (4) the curvature at $x = 0$ should vary with N as a power law,

$$C \equiv \left.\frac{d^2\Gamma}{dx^2}\right|_{x=0} \propto N^{2\alpha} \; . \tag{7}$$

This, of course, neglects corrections to scaling due to irrelevant variables and, indeed, a straight line fit to *all* the data does not yield an acceptable goodness of fit.

---

[c] Some extra conditions on the coefficients must be imposed to ensure that the model to be fitted to the data is unambiguous.

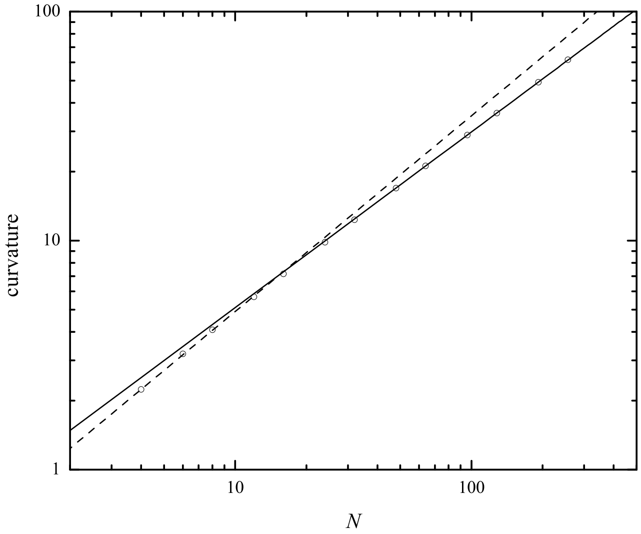

Fig. 3. The curvature C at $x = 0$ (see Eq. (7)), obtained from the polynomial fits shown in Figure 1, plotted as a function of N. The solid line is a straight line fit to the data for the largest five values of N. The slope corresponds to $\nu = 2.607$. The dashed line is a straight line with slope corresponding to $\nu = 2.34$ and passing though the $N = 4$ data point. The error in the data for the curvature is much smaller than the symbol size.

However, if data for $N \leq 48$ are excluded, acceptable goodness of fits are obtained. The estimates of the critical exponent obtained in this way are tabulated in Table 4.

In Fig. 3 we have also plotted two lines. One is a solid line that corresponds to the straight line fit for $64 \leq N \leq 256$. The second is a dashed line with a slope corresponding to the estimate of Huckestein[27] of the critical exponent and passing through the datum for the curvature at $N = 4$. While the main effect of the irrelevant corrections is the N dependent shift in the ordinate that is clearly visible in Fig.2, a smaller but not negligible effect on the curvature is also apparent in Fig.3. In our opinion, this is the reason why the critical exponent was underestimated in previous work. The precision of the numerical data was insufficient, and the range of N considered too small, for the irrelevant correction to be properly taken into account.

4. Comparison with the predictions of Lütken and Ross

The predictions of the theory of Lütken and Ross that can be compared with the present work are for the critical exponent and the leading irrelevant exponent. Their theory contains a single unknown parameter, the central charge c. In terms of this

Table 4. Estimates of the critical exponent ν obtained from linear fits of $\ln C$ versus $\ln N$.

range of N considered	ν	Confidence intervals ($\pm 2\sigma$)
$64 \leq N \leq 256$	2.607	$[2.598, 2.615]$
$96 \leq N \leq 256$	2.599	$[2.583, 2.616]$
$128 \leq N \leq 256$	2.590	$[2.586, 2.614]$

parameter they predict that the critical exponent is[d]

$$\nu = \frac{10.42050633345819\cdots}{c} \,. \tag{8}$$

In addition they predict that the leading irrelevant exponent and the critical exponent are related by

$$y = -\alpha = -1/\nu \,. \tag{9}$$

While we are not aware of any justification for this, assuming $c = 4$ gives

$$\nu = 2.60512\cdots \tag{10}$$

The most precise estimate in Table 4 is

$$\nu = 2.607 \pm 0.004 \,. \tag{11}$$

In fact, all of the estimates in Table 4 are consistent with the Lütken and Ross value. Turning to the irrelevant exponent, the situation is, unfortunately, much less clear. In Table 5 we tabulate some previous estimates of the irrelevant exponent. The Lütken and Ross prediction is

$$y = -0.383859\cdots \tag{12}$$

The estimate of Huckestein[27] is consistent with this but subsequent estimates by Wang et al.[29] are somewhat ambiguous. In our opinion, further confirmation is needed before reaching a conclusion.

Table 5. Estimates from the literature of the leading irrelevant exponent y and the quantities used to estimate it.

Huckestein [27]	$y = -0.38 \pm .04$	Lyapunov exponents
Wang et al.[29]	$y \approx -0.52$	geometric average of the two-terminal conductance
Wang et al.[29]	$y \approx -0.72$	arithmetic average of the two-terminal conductance

As mentioned above an unambiguous fit using Eq. (6) has not proved possible. The best we can do at present is to check the consistency of the Lütken and Ross values with our data by fixing both ν and y to these values when fitting. A series

---

[d] We noticed an error (a factor of 2) in Ref. 2. We thank Graham Ross for confirming this.

Table 6. Fits to the 379 data points shown in Figure 1.

n_0	n_1	number of parameters	χ^2	goodness of fit	Γ_c
3	3	16	398	0.10	$0.807 \pm .0005$
3	4	20	347	0.66	$0.804 \pm .0015$
3	5	24	343	0.67	$0.801 \pm .0035$

Table 7. Estimates of Γ_c obtained using published estimates of α_0 and Eq. (15)

	α_0	Γ_c
Obuse et al.[30]	2.2617 ± 0.0006	$0.8222 \pm .0019$
Evers et al.[31]	2.2596 ± 0.0004	$0.8156 \pm .0013$

of such fits are tabulated in Table 6. In the fits only a single irrelevant variable is assumed and non-linearities in the scaling variables are ignored, i.e.

$$v_0 = v_{02} x^2 \ \ , \ \ v_1 = v_{10} \ . \tag{13}$$

The scaling function is expanded as a Taylor series to order n_0 in the relevant field and order n_1 in the irrelevant field. One of the important quantities that can be estimated in this way is Γ_c, which is defined by

$$\Gamma_c = \lim_{N \to \infty} \Gamma\left(x = 0, N\right) = F\left(0, 0, \ldots\right) \ . \tag{14}$$

The quantity is significant because, if the quantum Hall critical theory has conformal symmetry, it is related to the multi-fractal exponent α_0 that occurs in the multi-fractal analysis of the wavefunction distribution at the critical point by

$$\Gamma_c = \pi\left(\alpha_0 - 2\right) \ . \tag{15}$$

Some estimates of Γ_c obtained using published estimates of α_0 and Eq. (15) are tabulated in Table 7. Our numerical estimate of Γ_c is not completely consistent with those in the table. The reason for this is not yet clear.

5. Discussion

The agreement between our estimate for the critical exponent and prediction of Lütken and Ross is tantalizing but is it accidental, or does it have a deeper significance? A more precise numerical estimate of the irrelevant exponent is clearly highly desirable. In addition, the prediction of Lütken and Ross for the flow diagram in the $(\sigma_{xy}, \sigma_{xx})$ plane should also be amenable to numerical verification. We also need to know if a central charge $c = 4$ is physically justified.

Quite apart from whether or not the Lütken and Ross theory is exact for non-interacting electrons, the important question remains of clarifying the role of the electron-electron interactions in the observed critical behavior at the quantum Hall transition. More work along the lines of Ref. 32 might be very helpful in this regard.

Acknowledgments

We would like to thank Alexei Tsvelik for bringing the work of Lütken and Ross to our attention. This work was supported by Grant-in-Aid 23540376 and Korean WCU program Project No. R31-2008-000-10059-0.
